Allenes, versatile unsaturated motifs in transition-metal-catalysed [2+2+2] cycloaddition reactions

A. Lledó, A. Pla-Quintana* and A. Roglans*

The development of efficient reactions that enable the construction of multiple bonds and/or stereogenic centres in a single synthetic operation is of great interest for greener and step-economical syntheses of complex organic targets. Transition-metal-catalysed [2+2+2] cycloadditions excel in this regard: no fewer than three new sigma bonds and a new ring system are formed from simple unsaturated components. Allenes constitute an important subclass among these. They are more reactive than simple alkenes and generate sp³ centres, with important stereochemical implications. In addition, further manipulation of the resulting cycloadduct through the remaining double bond is possible, increasing molecular complexity. This tutorial review highlights the value that allenes have as reagents in [2+2+2] cycloaddition and their great versatility for the development of methods to generate complex architectures.

Introduction

The construction of new ring systems is a key step in a multitude of organic syntheses. Among the strategies available to assemble cyclic frameworks, transition-metal-catalysed cycloadditions stand out as one of the most efficient options. A wide range of different six-membered rings can be efficiently built up by the transition-metal-catalysed [2+2+2] cycloaddition reaction,¹ a simplified representation of which is shown in Scheme 1. The reaction is remarkable in terms of the increase in molecular complexity, the functional group compatibility, the extremely high atom-efficiency, and the variety of substrates that can be used. On the other hand, the control of the chemo- and regioselectivity is the most critical aspect of this cycloaddition due to the large number of isomers that can be formed.

The [2+2+2] cycloaddition reaction can be catalysed by a wide range of early to late transition-metals. Despite the large number of complexes that can catalyse this transformation, the mechanism is postulated to be similar for complexes based on

Scheme 1 Transition-metal-catalysed [2+2+2] cycloaddition reaction to afford six-membered rings (M = transition-metal complex).

cobalt, rhodium, ruthenium, nickel, and iridium, which are amongst the most commonly used metals in these processes. Taking as an example the [2+2+2] cycloaddition of three alkynes, substrates in which the reaction was first described

Scheme 2 General overview of the mechanistic cycle of the [2+2+2] cycloaddition reaction of alkynes (M = transition-metal complex).

by Reppe *et al.*,² the mechanism can be summarised as outlined in Scheme 2.

Two alkynes sequentially displace metal-coordinated ligands to form alkyne complex **I**. Subsequent oxidative coupling results in the formation of either metallacyclopentadiene **IIa** or metallacyclopentatriene **IIb**. The coordination of a third alkyne substrate generates reactive species **III** from which alkyne insertion affords metallacycloheptatriene **IVa**. Alternative cycloadditions yield 7-metallanorborene complex **IVb** or metallabicyclo [3.2.0]-heptatriene **IVc**. Finally, the arene is formed by the reductive elimination of the metal and the catalyst is recovered after decooordination. The mechanistic cycle depicted in Scheme 2 has been validated by theoretical calculations^{3–5} and by the isolation of metallacyclopentadiene **IIa**⁶ and metallacyclopentatriene **IIb**⁷ intermediates. More advanced

intermediates in the catalytic cycle have also been detected.⁸ Slight variations in the mechanism (*i.e.* the intermediates formed) are invoked for different catalytic systems and/or substrates.

The problems of chemo- and regioselectivity that arise when differently substituted alkynes concur in the same reaction can be easily rationalised by the mechanism proposed. On the other hand, when the reaction takes place with at least one substrate that is different from an alkyne, the mechanism operating is assumed to involve analogous key steps and intermediates although it is often not clear at which step the different unsaturations enter the catalytic cycle.

Among the great variety of six-membered rings that can be formed, a large number of the reactions found in the literature describe the formation of aromatic rings, mainly benzene and pyridine (by reaction of three alkynes or two alkynes and a nitrile, respectively). Replacement of sp hybridised substrates by sp^2 hybridised ones generally concur with a decrease in reactivity, but has the advantage of allowing for the eventual introduction of stereogenic centres in the newly formed six-membered ring. This is exemplified for carbon-based unsaturations in Scheme 3, where the products that can be formed by the reaction of three alkynes or two alkynes and either an alkene or an allene are outlined. There are advantages and disadvantages in the use of the different carbon-based unsaturations. Alkynes readily participate in the reaction, allowing for the efficient synthesis of benzenes. The use of properly substituted alkenes allows for the synthesis of chiral cyclohexadienes. However, alkenes are more reluctant to react and, therefore, it is generally difficult to control the chemoselectivity given the high reactivity of the alkyne substrates. An excellent alternative to react sp^2 hybridised unsaturations, thus generating stereocomplexity, while maintaining the reactivity is the use of allenes.

Scheme 3 General scaffolds that can be obtained by [2+2+2] cycloaddition of two alkynes and either an alkyne, an alkene or an allene (M = transition-metal complex).

Allenes, which are cumulated systems with two contiguous carbon-carbon double bonds, are increasingly being used as substrates in many reactions.⁹ The development of efficient methodologies for the synthesis of a broad range of allenes has fostered their use as substrates.¹⁰ There are several particularities that make allenes especially appealing carbon-based unsaturated substrates in cycloaddition reactions. They have higher reactivity compared to alkenes and, when properly substituted, have inherent axial chirality. Both the electronic density and the reactivity of each carbon atom can be modulated by their substitution pattern. Furthermore, when allenes are reacted as two-carbon synthons, they deliver cycloadducts with an exocyclic double bond that can subsequently be manipulated. On the other hand, the use of allenes implies increased selectivity problems compared both to alkynes and alkenes. Apart from the chemoselectivity towards other unsaturations, and the issues of regio- and stereoselectivity, the chemoselectivity as to which of its two double bonds reacts also needs to be controlled.¹¹

Scope, limitation and organisation of the review

This review will cover all the transition-metal-catalysed or mediated [2+2+2] cycloaddition reactions involving allenes published up until October 2015. To be more concise, we have considered all works in which three new bonds are formed between an equal number of unsaturations to yield a six-membered ring, independently of whether the mechanism postulated follows the general scheme proposed in the introduction.

The review is organised by the type of unsaturations participating in the cycloaddition. Special attention has been paid to rationalise the selectivity of the reaction.

In all of the schemes in this review, specific case studies have been drawn, highlighting the point of diversity in red. The number of examples is given together with the range of yield.

Scheme 4 Pioneering studies of nickel catalysed cycloadditions with allenes.

Seminal studies

Pioneering studies into the use of allenes in metal catalysed cyclisations were first reported by Benson and Lyndsey¹² at DuPont in 1958 (Scheme 4). The authors found that the parent allene cyclotrimerised in the presence of nickel(0) catalysts in a moderate yield but with good selectivity *versus* cyclotetramerisation. The corresponding trimethylenecyclohexanes were obtained as a quasi-statistic mixture of 1,2,4 and 1,3,5 isomers (**1a–b**). Alternatively, the introduction of substoichiometric amounts of an alkyne in the mixture and the use of nickel(II) acetylacetonate gave dimethylenecyclohexenes **3** with good chemoselectivity, considering the large number of possible products.¹³ The experimental settings used (> 50 g scale, low boiling point of substrates and products) do not make these compounds particularly interesting for modern laboratory-scale research, but the chemoselectivities observed did anticipate the potential of allenes in cyclotrimerisation reactions. Notwithstanding, 35 years would go by before new examples of [2+2+2] cycloadditions involving allenes were reported by Malacria (*vide infra*).

[2+2+2] Cycloaddition reactions of three allenes

The cyclisation of three allenes was reinvestigated by Ma *et al.*^{14,15} in 2005, this time under Rh(I) catalysis and in a partially intermolecular setting, which constitutes an efficient entry into steroidal structures. In the presence of [RhCl(CO)(PPh₃)₂] as a catalyst, two molecules of a bis-allene **5** engaged in a cycloaddition to yield a cross-conjugated diene, which spontaneously underwent Diels–Alder cycloaddition with the remaining allene to yield tetracyclic compound **6** (Scheme 5). Remarkably, the [2+2+2] cycloaddition occurred with total chemoselectivity: the initial intramolecular oxidative addition step occurred through one terminal and one internal bond, while the second bis-allene incorporated reacted through the terminal position. Ma *et al.*¹⁶ later implemented this reaction in a combinatorial approach to

Scheme 5 Cyclisation of three allene unsaturations catalysed by Rh(I).

these steroidal compounds, employing mixtures of bis-allenes analogous to **5** with different tethers ($\text{C}(\text{SO}_2\text{Ph})_2$ in **5**). Not surprisingly, however, this strategy furnished mixtures of the four possible products with little selectivity and a preference for homocoupling products, if any.

Notwithstanding, the overall process was still completely chemo- and stereoselective, delivering a rapid increase in molecular complexity. A follow-up approach to this process consisted in combining a bis-allene and a mono-allene (Scheme 5).¹⁷ Under the right conditions (slow addition of bis-allene to excess mono-allene) selective cyclisation was achieved, delivering versatile diene products (**8**), which can be utilised in subsequent Diels–Alder reactions with a variety of dienophiles. The yields of this transformation were moderate but the reaction was relatively insensitive to variations in the structure of the allene **7**. Only one tether was reported, often a critical point of variation in these transformations. Overall, this tandem cycloaddition/Diels–Alder scheme provides an efficient and modular entry into tetracyclic steroid-like compounds.

[2+2+2] Cycloaddition reactions of allenes with carbon–carbon π -unsaturations

Intramolecular cycloadditions of allenes with alkynes and alkenes

In 1994, Malacria *et al.*^{18,19} started a series of studies employing allenes which prompted a revamped interest in the utility of these substrates in [2+2+2] cycloadditions. A number of linear allene–diyne substrates were prepared and tested for Co(I)-mediated

Scheme 6 Co(I)-mediated cycloaddition of allene–diyne substrates.

intramolecular cycloaddition (Scheme 6). Upon exposure to equimolar amounts of $[\text{CpCo}(\text{CO})_2]$ and under ultraviolet light activation, polyunsaturated yne–allene–yne substrates bearing tetrasubstituted allene moieties (**9/10**) cleanly underwent cycloaddition to yield tricyclic conjugated trienes, which were isolated as their corresponding η^4 cobalt complexes **11/12** and **13/14**. No reaction progress was observed when catalytic amounts of the cobalt complex were used.

Further efforts in this direction showed that allene substitution is key in this type of transformations, greatly affecting the outcome of the cycloaddition and its chemoselectivity. For instance, the cyclisation of analogous substrates bearing tri- or di- substituted allene portions (not shown) only met with failure under these conditions, most likely due to the instability of the resulting cyclisation products and intermediates. Analogous allene–diyne substrates **15** were also subjected to cycloaddition under the same conditions. Although the chemoselectivity is complete, it is quite erratic and difficult to predict beforehand. This transformation illustrates the strong effect of the allene substitution pattern on the reaction. With this particular arrangement of unsaturations, a trisubstituted allene exceptionally underwent clean cyclisation to **17a**. Generally speaking, complexes **11–14/16–17** are not particularly robust, and the reported silica promoted decomplexation to release the free triene products was low yielding and accompanied by alkene

isomerisation in most cases, somewhat diminishing the synthetic utility of this approach.

An interesting feature of these cyclisations is that they occur with effective axial to central chirality transfer, as demonstrated by Malacria *et al.*²⁰ in a separate study. When homochiral allene **18** (obtained from an enantiopure propargylic substrate) was subjected to the Co(I)-mediated cyclisation, the corresponding triene- η^4 -cobalt complex **19** was obtained as a single diastereoisomer without any erosion in enantiomeric excess (Scheme 7). It is worth noting that the introduction of a phosphine oxide group at the alkyne terminus was found to be beneficial for reaction yields. It was reasoned that this group increases the stability of intermediate reaction complexes. This function and similar ones (sulphones) have since been incorporated as a common structural motif of cycloaddition substrates in many related studies.

Malacria *et al.*^{21,22} later exploited the high chemo- and diastereoselectivity observed in these processes to access steroidal scaffolds in a straightforward manner. Based on the previous exploratory studies, the synthesis of a suitable precursor to the complete ABCD steroid ring system was addressed. Eventually, it was possible to obtain diastereomerically pure yne-allene-yne substrate **20**. Upon cyclisation, followed by silica-promoted decomplexation, steroid analogue **21** was obtained in moderate yield but with complete diastereoselectivity (Scheme 8). This approach allows a rapid increase in molecular complexity, but is hampered by difficulties in finding and accessing the appropriate cyclisation partner. In the case of other stereoisomers and close analogues of **20**, it was either not possible to isolate them in pure form or they did not give [2+2+2] cyclisation products.

In contrast to what is seen with allene-diyne cycloaddition precursors, the combination of an allene, an alkyne and an alkene appears to be more robust for intramolecular [2+2+2] cycloadditions. Saito, Sato *et al.*²³ first described the preparation of a series of allene-yne-ene substrates (**22**) and their cyclisation under ruthenium(II) catalysis (Scheme 9). Employing three-membered tethers between unsaturations, skipped diene products with a 5/6/5 ring system (**23**) were obtained with complete diastereoselectivity by selective reaction at the internal double bond of the allene. Moderate to good yields were obtained for most substrates with the exception of those bearing oxygen tethers. The process can be thus considered quite general and relatively insensitive to substitution

Scheme 7 Axial to central chirality transfer in a Co(I)-mediated allene-diyne cycloaddition.

Scheme 8 Diastereoselective synthesis of a steroid-like compound from a diastereomerically pure yne-allene-yne precursor.

at the reactive sp^2 positions, unlike previously discussed examples.

A similar study by Mukai *et al.*²⁴ inverted the order of the unsaturations in the cyclisation precursor, placing the allene moiety in the middle of the chain (**24**, Scheme 10). This arrangement proved to be extremely versatile in terms of structural variability and allowed the formation of complex tri- and tetracyclic scaffolds **25–30**, again in a totally diastereoselective fashion. In these cases, the authors employed a Rh(I) catalyst and obtained the corresponding products in good to excellent yields. The flexibility of this methodology is illustrated by the introduction of tethers of different lengths in the precursor structure, successfully leading to a variety of fused polycyclic systems of different sizes (compounds **26–30**, Scheme 10). An interesting feature of this approach is the possibility of forming a cyclopropane-fused polycyclic structure. The sole drawback of this strategy is the requirement for a *gem*-dialkyl substituted tether between the allene and the alkene moieties, which prevents undesired side reactions occurring through β -elimination processes of intermediate Rh(I) complexes.

The combination in a linear substrate of two allenes and a third different unsaturation is an interesting approach to polycyclic 1,3-diene products reported by our group (Scheme 11).²⁵ These cycloadducts have additional potential for increasing molecular complexity through successive cycloadditions. The Rh(I) catalysed cyclisation of allene-yne-allene and allene-ene-allene substrates (**31–32**) delivered cross-conjugated dienes **33–34** with complete chemo- and diastereoselectivity. In this case, the Wilkinson's catalyst, a convenient and practical source of Rh(I), was used.

Additionally, detailed DFT calculations were carried to rationalise the observed diastereoselectivity and to propose a

Scheme 9 Ru(II)-catalysed cycloaddition of allene-yne-enes.

Scheme 10 Rh(I)-catalysed cycloaddition of ene-allene-yne.

mechanistic cycle. After a detailed analysis of the many possibilities for the key reaction intermediates, oxidative addition was postulated as taking place between the central alkene and the internal double bond of one of the allenes, leading to a *cis*-fused bicyclic intermediate **VI**. The remaining allene is then inserted into the Rh-Csp³ bond of the rhodacyclopentane in **VI** to give a *trans* fused ring junction in intermediate **VII** (Scheme 12). The preference for cyclisation at the internal

Scheme 11 Rh(I)-catalysed cyclisation of allene-yne/ene-allene substrates and the Diels-Alder adducts obtained.

Scheme 12 Key intermediates proposed on the basis of DFT calculations in the Rh(I) catalysed cyclisation of allene-ene-allene substrates.

double bond of the allene was also analysed. This concurred with a higher energy of the occupied π molecular orbital localised at this double bond. It is worth mentioning that this is the first and only example in which a mechanistic hypothesis has been validated by rigorous computational techniques. Finally, the products obtained easily engaged in Diels-Alder reactions with maleimide, delivering complex pentacyclic products **35/36** in excellent yields and with total stereoselectivity.

Two additional examples of intramolecular cyclisation are found in the literature, although they are of lesser synthetic interest. In the context of a study on rhodium-catalysed carbonylative cycloaddition reactions, Ojima *et al.*²⁶ found that allene-diyne **37** underwent regular [2+2+2] cycloaddition (without CO insertion) and concomitant isomerisation to yield the corresponding benzo-fused tricyclic product **38** (Scheme 13). A similar result was observed by our research group.²⁷ Allene-diyne **39** bearing a longer tether gave, in the presence of Wilkinson's complex, tricyclic benzene scaffold **40**. Although both reactions proceed selectively at the outer double bond of the allene, its utility is somewhat limited: in a completely intramolecular setting, the same structures can be easily accessed employing analogous triyne precursors.

Intermolecular and partially intermolecular cycloadditions of allenes with alkynes

The viability of the intermolecular [2+2+2] cycloaddition of allenes with alkynes was first established in two papers by

Scheme 13 Rh(I)-catalysed cyclisation/isomerisation of allene-diyne to obtain benzo-fused tricyclic compounds.

Scheme 14 [2+2+2] Cycloadditions between monoalkynes and diynes with allenes.

Dieck *et al.*^{28,29} While studying the synthesis of naphthalene derivatives they found that a diazadiene stabilised palladacyclopentadiene was able to catalyse the [2+2+2] cycloaddition of an allene with two equivalents of dimethyl acetylenedicarboxylate **41** but only in the specific case in which phenoxyallene **42** was used (Scheme 14a).²⁸ When increasing the temperature to 60 °C and increasing the catalyst loading, the benzene derivative was obtained quantitatively.²⁹ The authors postulate that the benzene derivative is formed after an isomerisation process of the initially formed 1,3-cyclohexadiene derivative.

Takahashi *et al.*³⁰ also used a metallacyclopentadiene for the [2+2+2] cycloaddition reaction although in this case as a substrate. In the framework of a study into nickel-mediated cycloadditions of zirconacyclopentadienes **44** with alkynes, two allenes were tested in the process. The reaction was not chemoselective as they obtained a mixture of isomers **46** and **47** from the addition of each of the two double bonds of the allene (Scheme 14b). The authors proposed a mechanism consisting of a transmetalation step from the zirconacyclopentadiene to form the corresponding nickelacyclopentadiene followed by the insertion of the allene and, finally, reductive elimination and isomerisation.

Cheng *et al.*^{31–33} made a substantial contribution to the topic by systematically studying the intermolecular cycloaddition of allenes with alkynes and diynes (Scheme 15). In these studies, the less substituted double bonds of the allenes were found to participate in the cycloaddition. Presumably, the first compound obtained in these processes was the 1,3-cyclohexadiene derivative, which was followed by an isomerisation/aromatisation process to afford the corresponding benzene compound. Therefore, the allenes acted here as synthetic equivalents of mono-substituted alkynes. The first study by Cheng *et al.*³¹ was based on a completely intermolecular reaction between two molecules of alkyne and one molecule of allene under nickel catalysis, to

Scheme 15 [2+2+2] Cycloadditions between monoalkynes and diynes with terminal allenes.

afford polysubstituted benzene derivatives in a highly regio- and chemoselective fashion (Scheme 15a). The best catalytic system found was [Ni(dppe)Br₂] with an excess of metallic Zn as the reductant of Ni(II) to Ni(0), which was the actual catalytic species. With a ratio of 2:1 of starting materials **49**:**48** no cyclotrimerisation of the alkyne was observed. The presence of an ester group in the alkyne was necessary for the success of the reaction. Remarkably, the reaction was highly selective and only isomer **50** was observed. Curiously, when the propiolate had an aryl group attached, products with different regiochemistry were obtained.

This first study was later on extended to the cycloaddition of diynes with allenes.^{32,33} The partially intermolecular version is often more advantageous in the control of the regioselectivity of the cycloaddition. The same Ni-based catalytic system as before was used (Scheme 15b). Homocoupling of the diyne was not observed even when a stoichiometric ratio of starting materials was used. When the diyne was not symmetrical (**51b**), the cycloaddition was highly regioselective, giving the *meta*-isomer **52b** as the predominant compound. The presence of an ester group in the diyne was again necessary. The use of [CoI₂(PPh₃)₂]/Zn system, instead of nickel complexes, improved the reaction broadening the cycloaddition scope to electronically neutral diynes (**51c–d**). The cycloaddition also resulted in

high chemo- and regio- selectivity (Scheme 15b). The authors demonstrate the advantages of allenes in comparison with analogous alkynes by performing the reaction with 1-heptyne instead of its isomeric derivative, *n*-butylallene (**48**), obtaining, in all cases, a mixture of compounds and much lower yields of the desired product.

The mechanistic proposal for these cases follows the general scheme commented in the introduction, with the allene entering in the last step of the catalytic cycle. The *meta*-regioselectivity is justified by steric hindrance of the intermediate leading to the *ortho*-isomer.

Cheng *et al.*³⁴ made a further contribution using the previously mentioned nickel catalytic system to trigger the [2+2+2] cycloaddition between an allene and two arynes (Scheme 16a). While arynes have been reacted with a variety of alkynes, diynes, allyl derivatives and CO under palladium catalysis to afford [2+2+2] cycloadducts,³⁵ this was the first time that they were reacted with allenes. The arynes were generated *in situ* by fluoride-induced β -elimination of *ortho*-(trimethylsilyl)benzene

triflates. An allene was reacted with two equivalents of the *in situ* generated benzyne to provide 10-methylene-9,10-dihydrophenanthrene derivatives **55** in an efficient and selective manner (Scheme 16a). In contrast to the previous studies by the same group, the monosubstituted allenes reacted through the internal double bond, giving a highly chemoselective reaction. However, when the allenes were 1,1-disubstituted a mixture of the two isomers was formed, which the authors attributed to steric effects. Another difference of this study in comparison with earlier ones is that the exocyclic double bond in the cyclohexadiene initially generated did not undergo isomerisation to give the more stable aromatic derivative. This exocyclic double bond is maintained in the final cycloadduct **55**. Phenylallene failed to react, and only alkyl substituents were tolerated on the allene and only terminal allenes were tested. Small amounts of the homotrimerisation product of benzyne were observed in all of the reactions. These studies would seem to show that both the chemoselectivity of the process and the isomerisation step are quite unpredictable.

Later Liang, Li *et al.*,³⁶ following on from Cheng, studied the synthesis of phenanthrene derivatives by the cycloaddition of allenes with two molecules of arynes but under palladium catalysis (Scheme 16b). After optimisation, the [[allyl]PdCl]₂/P(*o*-Tol)₃ catalytic system was found to be the most efficient. When they tested 1,3-disubstituted allenes **56** with an electron-withdrawing group, the final product was the benzene derivative **57** obtained after the isomerisation step. The reaction was highly chemoselective as it took place with the double bond not linked to the electron-withdrawing group. Using trisubstituted allenes and alkyl terminal allenes, the authors obtained the same tricyclic derivatives **55** as Cheng without aromatisation. Here again it seems to be rather difficult to predict the final product in these processes and probably both electronic and steric effects play an important role in the process as a whole.

Fluoride-induced β -elimination of *ortho*-triflate **58**, was also used by Peña, Guitián *et al.*³⁷ for the *in situ* preparation of 1,2-cyclohexadiene, a highly reactive and strained bent allene. In order to study the reactivity of this cyclic allene, precursor **58** and dimethyl acetylenedicarboxylate were treated with catalytic amounts of [Pd(PPh₃)₄] in the presence of CsF, affording a mixture of benzene derivatives **59** and **60** in 10 and 19% yields, respectively (Scheme 16c). The authors proposed a palladium-catalysed [2+2+2] cycloaddition reaction between the cyclic allene and two molecules of alkynes followed by a fluoride-induced deprotonation/aromatisation to give derivatives **59** and **60**.

Another example by Ma *et al.*³⁸ of [2+2+2] cycloaddition reactions involving alkynes and allenes is the dimeric cycloaddition of propargylic 2,3-dienoates **61** catalysed by a modified Wilkinson complex (Schemes 17 and 18). A [2+2+2] cycloaddition took place between the propargylic triple bond, the remote double bond of the allene moiety and the triple bond of a second molecule of the propargylic dienoate **61**. The 1,3-cyclohexadiene **62** obtained in a first stage, underwent an intramolecular Diels-Alder reaction to afford tricyclic derivative **63** in good yields. Although **63** has four stereogenic centres, only two diastereoisomers were formed, which could be separated by column chromatography (Scheme 17).

Scheme 16 [2+2+2] Cycloadditions involving benzyne and 1,2-cyclohexadienes.

Scheme 17 Rh(I)-catalysed bimolecular cyclisation of propargylic allenates.

Certain specific substrates delivered, under the optimised reaction conditions, monocyclic dihydropyranone derivatives rather than the expected cycloadducts. This prompted the authors to study the process mechanistically. The substituents at the 4-position of the starting allenate moiety (R_1 and R_2) were found to control the reaction course (Scheme 18). The rhodacyclopentene formed after the oxidative addition between the alkyne and the remote double bond of the allene (intermediate **VIII** in Scheme 18) can evolve through two different pathways depending on the substituents on the allene: (i) a β -H elimination to afford monocyclic dihydropyranone derivatives **64**;

Scheme 18 Mechanistic proposal for the Rh(I)-catalysed unimolecular and bimolecular cyclisations of propargylic allenates.

or (ii) an alkyne insertion to deliver the [2+2+2] cycloadduct when the substituent at the 4-position did not have a β -H atom. The mechanistic proposal for both pathways was confirmed by trapping intermediate **VIII** with 3-methoxyprop-1-yne to afford derivative **65**.

Partially intermolecular cycloadditions of allenes with alkenes

Allenes were also reacted with alkenes. In this respect, Alexanian *et al.*^{39–41} studied the partially intermolecular rhodium-catalysed [2+2+2] cycloadditions of ene-allenes with allenes and alkenes, respectively, to afford carbocycles with up to four contiguous stereogenic centres, including quaternary stereocentres.

In their first study,³⁹ the cycloaddition between ene-allenes substrates **66** and monosubstituted allenes **67** afforded regio- and diastereoselectively *trans*-fused carbocycles **68** with up to four stereogenic centres (Scheme 19). The substituted double bonds of the two allene moieties were involved chemoselectively in the cycloaddition, affording an *exo*-hexacyclic diene **68**. After some experimentation the optimal catalytic system was found to be a rhodium chloride dimer with H_8 -BINAP ligand treated with silver salts in order to generate *in situ* a cationic rhodium complex. Several tethers in **66** were tolerated, as well as different substituents in the alkene moiety. The use of trisubstituted alkenes (**66b**) produced cycloadducts containing a quaternary stereocentre (**68b**). No substituents were introduced on the tethered allene and the scope of the second allene was limited to ethyl allenate and phenyl allene. The mechanistic proposal was based on the initial oxidative addition between the two substituted double bonds of the allene moieties and when the alkene is inserted in the corresponding rhodacyclopentane, the *trans* ring fusion was established. An extension of this study was to investigate the enantioselectivity of the cycloaddition.⁴⁰ Therefore, with the same substrates **66** and

Scheme 19 [2+2+2] Cycloaddition reactions between ene-allenes and allenes or alkenes.

monosubstituted allenes, the reaction was studied using (*R*)-H₈-BINAP as the chiral ligand with the same rhodium-based catalytic system. On comparing this ligand with 39 chiral BINAP-type ligands they found that (*R*)-H₈-BINAP was the most efficient. The enantiomeric excess of the cycloadducts obtained ranged from 48 to 74%.

The cycloaddition of ene-allenes **66** with electron-poor alkenes was also studied by the same research group (Scheme 19).⁴¹ The optimal rhodium-based catalytic system used in the two previous studies did not catalyse the [2+2+2] process in this case. Therefore, the authors turned to nickel complexes and found that the combination of [Ni(COD)₂] with monophosphine P(*o*-Tol)₃ was the best catalytic system to afford regio- and diastereoselectively *cis*-fused carbocycles **70** in good yields. An excess of alkene and a slow addition of the ene-allene to the reaction mixture improved the yield. Different tethers in **66** were also tolerated. No substituents were introduced on the tethered allene, which also reacted with the inner double bond, and the alkenes were always electron-poor. Interestingly, the process seems to be highly sensitive to the nature of the phosphine used as a ligand. When P(^{*t*}Bu)₃ was used instead of P(*o*-Tol)₃, the reaction led to an alkenylative carbocyclisation process and when a bidentate phosphine such as XANTPHOS was used, an ene-allene [2+2] cycloaddition took place. In neither case was [2+2+2] cycloadduct observed.

[2+2+2] Cycloaddition reactions of allenes with carbon-heteroatom π -unsaturations

One of the most interesting advances in the field of [2+2+2] cycloadditions is the involvement of heteroatoms to the generation of different types of heterocycles. Murakami *et al.*⁴² studied the reaction of allenes with heterocumulenes such as isocyanates. In a completely intermolecular version, the authors described the cycloaddition of one molecule of allene with two molecules of isocyanates to afford dihydropyrimidine-2,4-dione derivatives (**73/74**) under nickel(0) catalysis (Scheme 20). This is not an easy process given that it is necessary to control both the chemoselectivity, which was achieved using an excess of the isocyanate, as well as the double bond of the allene involved in the reaction. In the case that the main isomer was derivative **73**, a stereogenic centre would be created. When the (*S,S*)-^{*i*}Pr-Foxap chiral ligand, an unusual ligand for enantioselective [2+2+2] cycloaddition reactions, was used, regioisomer **73** was predominantly formed (**73**:**74** > 20:1) in high enantiomeric excess. The use of bidentate ligands was crucial for the success of the reaction. Only alkyl terminal allenes and aryl isocyanates were tested to cover the scope of the process. Remarkably, this was the first reported example of enantioselective [2+2+2] cycloaddition involving allenes.

Another heteroatom that has been involved in cycloadditions with allenes is the carbonyl group of aldehydes and ketones to afford compounds with a pyran ring in their structure. Oonishi, Sato *et al.*⁴³ constructed tricyclic pyran

Scheme 20 Ni(0)/(*S,S*)-^{*i*}Pr-Foxap catalysed enantioselective [2+2+2] cycloadditions between allenes and isocyanates.

derivatives **76** in a stereoselective manner from acyclic allene-yl aldehydes **75** (Scheme 21).

Given that one of the competing pathways is the cyclopropanation/cyclisation of the allenyne moiety⁴⁴ to afford derivatives **77**, screening of the reaction conditions was undertaken. Curiously, the use of phosphine and NHC-carbene ligands were detrimental to the process as the best combination was [Rh(COD)Cl]₂/AgBF₄ in DCE at room temperature. However, the process was highly sensitive to the nature of lineal substrate **75**. When there were four methylene units between the triple bond and the aldehyde, the competing pathway opened up to form **77**. When there were two methylene units between the allene and the tether, a rearrangement of the 5-alkynyl moiety in the substrate took place. The process was chemoselective to the double bond of the allene with the ^{*t*}Bu substituent. The formation of the *syn*-isomer was justified mechanistically to avoid steric repulsion between the substituent of the allene and the α -CH₂ of the carbonyl group when the aldehyde was inserted into the rhodacyclopentene intermediate.

The same authors^{45,46} studied the rhodium-catalysed cyclisation of analogous acyclic derivatives **78** and **79** in which the allene was placed in the middle of the chain, and the heteroatom was a C=O group (**78**) or an imine (**79**) (Scheme 22). In both cases, when the allenyne compounds did not have a hydrogen atom at the β -position of the carbonyl or sulphonylimine moieties, pyran and piperidine derivatives

Scheme 21 Rhodium-catalysed intramolecular [2+2+2] cycloaddition reactions of allenes involving aldehydes.

Scheme 22 Rhodium-catalysed intramolecular [2+2+2] cycloaddition reactions of allenes involving aldehydes and imines.

containing fused five and seven-membered rings **80** and **81** were obtained respectively in good yields. In the case of **78**, alkyl, aryl and silyl ketones covered the scope of the process. In the case of sulfinylimines **79** the scope was tested with different substituents of the alkyne such as hydrogen, alkyls, esters, a phenyl and a TMS group. In both cases, when the starting lineal substrates had a hydrogen atom at the β -position of the carbonyl or sulfinylimine moieties, the rhodacycle intermediate suffered a β -hydride elimination giving 5,7-fused cyclic alcohols **82** and amides **83**, respectively (Scheme 22).

If we analyse the different outcome of allenes **75** in comparison with **78/79**, we can deduce that the selective insertion of the carbonyl bond to the Rh-Csp² bond of the rhodacyclopentene intermediate determines the nature of the final product. In the case of **78** and **79**, the reaction proceeds through a strained transition state **XI** to afford intermediate **XII** (Scheme 23).

Pursuing the same idea as Oonishi and Sato, Tanaka *et al.*⁴⁷ designed a partially intermolecular enantioselective version of tosylamide-linked 5-allenyl **84** and 5-allenone with internal alkynes **85** under rhodium catalysis to afford 3,4-dihydropyran derivatives **86** (Scheme 24). In this case, the best catalytic system was found to be a combination of 20% molar of cationic complex [Rh(COD)₂]BF₄ with the chiral ligand (*S*)-BINAP. The scope of the process was quite limited since the alkynes had to be non-terminal and a tosyl linker was necessary in the starting material. Surprisingly, the regioselectivity of the process seems to be erratic although the enantioselectivity was good.

Oonishi, Sato *et al.*⁴⁸ later studied the same reaction, the cycloaddition of allenyl aldehydes **84** with alkynes under rhodium catalysis, broadening the scope of the allenyl derivative: other tethers were used instead of the tosyl group, the carbon chain between the allene and the aldehyde moieties was elongated and an aromatic ring was added to the tether.

Scheme 23 Mechanistic proposal for intramolecular [2+2+2] cycloaddition reactions of allenynes and aldehydes.

Internal alkynes with an electron-rich aromatic ring and an electron-withdrawing group (**85b**) were efficient although symmetrical alkynes did not react. The process was regio- and enantioselective using (*R*)-SEGPHOS as the chiral biphosphine. As in the study by Tanaka, terminal alkynes did not work and, in this case, diene ketones were obtained instead of cycloaddition products. The authors proposed an initial oxidative addition between the internal double bond of the allene and the carbonyl group of **84** generating an oxarhodacyclopentane followed by the insertion of the alkyne. The regioselectivity

Scheme 24 Rhodium-catalysed partially intermolecular [2+2+2] cycloaddition reactions of allenes involving aldehydes.

Scheme 25 Wilkinson's complex-catalysed [2+2+2] cycloadditions of acyclic allene–yne–cyano derivatives.

observed in the insertion step was justified by electronic effects of the alkyne.

One contribution of our research group was to involve nitriles in [2+2+2] cycloadditions with allenes to generate 2,6-naphthyridine scaffolds **89** for the first time (Scheme 25).²⁷ The use of Wilkinson's catalyst allowed the chemoselective reaction of allenes through their external double bond to give unsaturated pyridine-containing scaffolds **88** after a dehydrogenative step. After some experimentation, it was found that it was necessary to use a catalytic amount of Et_3N and microwave rather than conventional heating in order for the reaction to proceed successfully. Removal of the tosyl group allowed entry into 2,6-naphthyridine nuclei, as is seen in derivative **89**.

Miscellaneous cycloadditions

In this section we will comment on studies in which products are reported that present structures (six-membered carbo- or heterocycles) which come from formal [2+2+2] reactions of three unsaturations, but which mechanistically display different patterns.

Ma *et al.*⁴⁹ disclosed a palladium-catalysed cyclisation of diyne carbonates **90** and allenic acids **91** (Scheme 26). The reaction is applicable to both secondary and tertiary carbonates with different tethers between the alkynes, and the alkyne in a remote position with respect to the carbonate may be terminal or non-terminal. When a stereogenic centre was introduced in the propargylic position, the chirality was not erased in the course of the reaction. With respect to the allenic acids, aryl, alkyl and allyl substituents were tolerated. When 4-monosubstituted allenic acids were used, the initial cycloadduct suffered an isomerisation to deliver aromatised compounds.

The authors postulate a mechanism for the transformation (Scheme 27) consisting of initial oxidative addition and cyclic carbopalladation of the diyne carbonate to form a 1,3,4-trienyl methoxide palladium intermediate **XIII**. A subsequent *trans*-oxopalladation generates a palladacyclopentadiene **XIV** in which the ester has already been formed. From this point, the mechanism is analogous to that which is presented in the

Scheme 26 Palladium-catalysed cyclisation of diyne carbonates and allenic acids.

Scheme 28 Au-catalysed [2+2+2] cycloaddition reactions of allenamides, alkenes and aldehydes.

introduction, *i.e.* insertion of the electron-rich double bond of the allene, followed by reductive elimination.

Another study by Mascareñas, López *et al.*⁵⁰ describes the fully intermolecular [2+2+2] cycloaddition of three different components such as allenamides **93**, alkenes **94** and aldehydes **95** to afford tetrahydropyrans **96** under gold catalysis (Scheme 28). The authors found that a phosphite gold complex catalysed the cycloaddition at very low temperatures (-45°C or -78°C) in a high regio- and 2,6-*cis* diastereoselective fashion. The scope of the process is extremely broad: alkenes, styrenes, cyclic alkenes, and electron-rich alkenes were used as alkenes; for aldehydes, benzaldehyde and

Scheme 29 Key intermediates proposed for the Au-catalysed [2+2+2] cycloaddition reactions of allenamides, alkenes and aldehydes.

alkylaldehydes; for allenamides, γ -methyl-substituted allenamides and *N*-tosylphenyl allenamides.

The authors proposed an initial π -activation of the allene by the gold complex to form the conjugated acyliminium intermediate **XV**, which undergoes 1,4-addition by the alkene, giving intermediate **XVI**. The nucleophilic attack of the carbonyl group of the aldehyde led to intermediate **XVII** and finally to cycloadduct **96** (Scheme 29).

Conclusions

Allenes are versatile reaction partners in transition-metal-catalysed [2+2+2] cycloadditions for a number of reasons. They display a good reactivity profile, rivalling that of alkynes and far superior to the sluggish reactivity of alkenes. Moreover, cycloadditions involving allenes proceed with good stereoselectivities and much improved chemo- and regioselectivities with respect to all-alkyne cycloadditions. The latter is advantageous for the implementation of intermolecular multicomponent reactions. However, the nature of the chemo- and regioselectivity is highly dependent on the allene structural environment and is difficult to predict. Special care must be taken in the choice of substrates and the design of polyunsaturated precursors, in order to avoid detrimental β -elimination processes. The analysis of the potential mechanistic scenarios by computational techniques may be a solution to these shortcomings. As we progress in the understanding of such intricacies, [2+2+2] cycloadditions involving allenes should gradually find use in target-oriented applications.
