HIGHLIGHTS

• Information on the effects of water scarcity on river ecosystems is necessary.
• Multiple stressors should be considered.
• The GLOBAQUA project is designed to satisfy these demands.
• The general structure of the EU FP-7 project GLOBAQUA is outlined.

ABSTRACT

Water scarcity is a serious environmental problem in many European regions, and will likely increase in the near future as a consequence of increased abstraction and climate change. Water scarcity exacerbates the effects of
1. Introduction

Water is one of the most essential natural resources, and water-related services are major components of human wellbeing and key factors for socio-economic development (UNEP, 2007). Nowadays, freshwater ecosystems are under threat from the effects of multiple stressors, including organic and inorganic pollution, geomorphological alterations, land use changes, water abstraction, invasive species and pathogens (Vörösmarty et al., 2010). Although the interaction between stressors can result in complex effects on organisms (Coors and De Meester, 2008), and ultimately on ecosystems (Ormerod et al., 2010), little is known beyond the described effects of single stressors on the chemical and ecological status of water bodies and on their ecosystem functionality. This lack of knowledge limits our capacity to understand ecosystem responses to multiple stressors (Friberg, 2010).

Water scarcity is a key stressor in many river ecosystems as it tends to exacerbate the detrimental effects of other stressors, for instance by increasing the concentration and the ecological effects of pollutants (Petrovic et al., 2011). Water scarcity is particularly important in semi-arid regions such as the Mediterranean area (Ludwig et al., 2011; European Environmental Agency, 2012), but also in other regions where water demand approaches, or even exceeds, water availability. This includes large areas of Europe, as can be gleaned from the Water Exploitation Index (WEI), defined as the ratio of all annual abstractions over inter-annual resources (Barcelo and Sabater, 2010; European Environmental Agency, 2012). Although the main uses of water differ markedly on a regional basis (mainly agriculture in semi-arid regions, hydropower in wet mountain regions, industrial and urban uses in densely populated areas (Haddeland et al., 2013)), water demand is rising across most of the world (Steffen et al., 2011). At present there are over 45,000 large dams and over 800,000 smaller dams (Nilsson et al., 2005), in addition to extensive waterways and systems for groundwater abstraction (Acreman et al., 2000). In many regions water consumption is much higher than water availability (Boithias et al., 2014), a situation that can only be maintained by means of water transfers from other basins. Scenarios of future climate change predict increased water scarcity in large areas, including the Mediterranean basin (IPCC, 2014), as well as an increase in the magnitude of extreme floods and droughts (Dankers and Feyen, 2008). Regulation, diversion and abstraction of water are expected to increase in the near future in response to climate change and human population growth (poff et al., 2003; Palmer et al., 2008; Finer and Jenkins, 2012). Therefore, the ecological and societal impacts of water scarcity can be even larger in the near future.

Water scarcity has become one of the most important drivers of change in freshwater ecosystems across the world. It is estimated that by 2025 about 1.8 billion people will be living under absolute water scarcity, and that two-thirds of the world’s population could be under serious conditions of water stress — the threshold for meeting the water requirements for agriculture, industry, domestic purposes, energy and the environment (UNEP, 2007). The joint occurrence of a myriad of stressors (chemical, geomorphological, biological) under water scarcity may produce novel and unfamiliar synergies and, most likely, very pronounced effects of unknown consequence. Further, water authorities rely on incomplete information to implement long-term strategies to mitigate the deleterious effects of these complex interactions. Water scarcity compromises the implementation of water policies and impair the capacity of taking sound management decisions (Poens and Hooke, 1997; Baron et al., 2002; Acuña et al., 2014). Furthermore, current management practices and policies often neglect the influence of multiple stressors on ecosystem services, and fail to appreciate the importance of future water scarcity. The limited information on the biophysical and economic values of ecosystems and the alterations they undergo as a consequence of global change limits the capacity of decision-makers to improve current policies. Human economy and social equilibrium also depend on the wise management of declining availability of fresh water resources. Therefore, it is urgent to gain scientific information on the potential effects of water scarcity on river ecosystems under multiple stressors, to understand how these will in turn affect ecosystem services, and to transfer all this knowledge into sound policies that can minimise the impacts of ongoing global change. The GLOBAQUA project is designed to satisfy these demands.

The objectives of this paper are to present an overall picture of the GLOBAQUA project, its structure, and to present an overview of the six river basins studied.

2. The GLOBAQUA project

GLOBAQUA is a project funded by the Seventh EU Framework Programme under the full title Managing the effects of multiple stressors on aquatic ecosystems under water scarcity. It is active since February 2014 and will continue until January 2019. It assembles a multidisciplinary team of hydrologists, chemists, biologists, geomorphologists, economists and sociologists, including experts in modelling, in socio-economics and governance science, and in knowledge brokerage and policy advocacy. GLOBAQUA comprises 21 partner organisations from 9 EU countries as well as one Associated Country (Serbia) and 2 non-EU partners (Morocco and Canada). Scientific, financial and administrative management of the project is carried out by the Institute of Environmental Assessment and Water Research of the Spanish Council of Scientific Research (IDAEA-CSIC). The team involves researchers, but also practitioners and end-users such as policy-makers and river basin managers.

The main aim of GLOBAQUA is to study the effects of water scarcity in a multiple stressor framework to achieve a better understanding of multiple stressors, and thus results in decreased water quality. It impacts river ecosystems, threatens the services they provide, and it will force managers and policy-makers to change their current practices. The EU-FP7 project GLOBAQUA aims at identifying the prevalence, interaction and linkages between stressors, and to assess their effects on the chemical and ecological status of freshwater ecosystems in order to improve water management practice and policies. GLOBAQUA assembles a multidisciplinary team of 21 European plus 2 non-European scientific institutions, as well as water authorities and river basin managers. The project includes experts in hydrology, chemistry, biology, geomorphology, modelling, socio-economics, governance science, knowledge brokerage, and policy advocacy. GLOBAQUA studies six river basins (Ebro, Adige, Sava, Evretas, Anglian and Souss Massa) affected by water scarcity, and aims to answer the following questions: how does water scarcity interact with other existing stressors in the study river basins? How will these interactions change according to the different scenarios of future global change? Which will be the foreseeable consequences for river ecosystems? How will these in turn affect the services the ecosystems provide? How should management and policies be adapted to minimise the ecological, economic and societal consequences? These questions will be approached by combining data-mining, field- and laboratory-based research, and modelling. Here, we outline the general structure of the project and the activities to be conducted within the fourteen work-packages of GLOBAQUA.

© 2014 The Authors. Published by Elsevier B.V. This is an open access article under the CC BY-NC-ND license (http://creativecommons.org/licenses/by-nc-nd/3.0/).
how current management practices and policies could be improved by
identifying their main drawbacks and alternatives (Fig. 1). More spe-
cifically, the project goals are:

• To understand the effects of water scarcity on the impacts of multiple
stressors in selected case studies. Six contrasting river basins where
water scarcity is a present or potential issue are being studied, and
their main stressors are being identified. Field and laboratory experi-
ments as well as modelling exercises will be performed to understand
the effects of water scarcity on the environmental consequences of the
identified stressors.

• To predict how these interactions will be altered according to different
scenarios of future global change. The drivers of land use change and
water management are being determined for each basin, and models
will be used to assess integrated scenarios, taking into account
projected changes of climate and socioeconomic measures at the
river basin scale. Detecting the current hydrological trends and fore-
casting the future status of water resources require determining the
nature of changes in surface and subsurface hydrological fluxes, cou-
pling hydrological and biogeochemical models.

• To analyse the consequences of oncoming changes on biodiversity
and ecosystem functioning. The effects of multiple stressors on biodi-
versity and ecosystem functioning are difficult to predict because of
synergies, feedback and cross-amplification among stressors. Observa-
tional and experimental data will be combined to analyse the ef-
facts of nutrients, contaminants, degraded physical habitat and
water scarcity on river biodiversity and ecosystem functioning.
Models will be used to forecast further declines in biodiversity and as-
associated changes in ecosystem functioning.

• To analyse the effects of water scarcity on ecosystem services in the
study basins. The implications of socio-economic development will
be analysed to provide an economic and social valuation of ecosystem
services, taking into account the user perspective. Thresholds will be
identified beyond which water scarcity and multiple stressors would
threaten ecosystem services and make it impossible to satisfy water
demands.

• To explore how to adapt management and policies to minimise the
ecological, economical and societal consequences of ongoing global
change. Scientific results from the above objectives will be integrated
with the demands of policymakers and national/EU environmental
agencies to fill the communication gap in the Science–Policy Interface,
by providing a user perspective.

3. Case studies

GLOBAQUA assesses the effects of water scarcity on aquatic eco-
systems and their services by focusing on six contrasting river ba-
sins, and by following a cross-scale approach. The basic research
element is the kilometre-scale river reach, including the river chan-
nel, the alluvial plain and the associated groundwater. Two basins
from the Mediterranean European region (Ebro — Spain and Evrotas
— Greece), as well as one north African basin (Souss Massa — Morocco),
where water scarcity is the main current problem, have been selected
to obtain a Mediterranean perspective. In order to achieve a wider
European dimension, one continental (Sava, transboundary — Slovenia,
Croatia, Bosnia and Herzegovina and Serbia), one Alpine (Adige
— Italy) and one UK river basin (Anglian River basin district), where scar-
city is a growing issue because of multiple uses and unequal yearly distri-
bution of precipitation, have been included among the case studies. The
selected basins encompass a rich set of socio-ecological conditions (for-
ested mountainous areas, highly populated regions relying on water
transfers, agricultural areas and industrial clusters), and a wide geo-
graphic coverage (Fig. 2), but are all affected by water scarcity due to ei-
ther climatic or societal factors. Each basin focuses on a specific set of
stressors to illustrate different management scenarios. In four of them
(Adige, Sava, Ebro and Evrotas) extensive field work will be done,
while in two of them (Anglian River basin district and Souss Massa)
the existing data will be used to evaluate different management
scenarios.

The Ebro is the largest Mediterranean Spanish river, 928 km in
length and with a drainage basin of 85,550 km² (Sabater et al.,
2009). Hydrology is markedly seasonal, with high flow peaks and
long periods of low flow, and is severely affected by water scarcity.
The Ebro is also extremely regulated by dams and channels, and
includes important agricultural areas, as well as several industrial
cities that host 45% of the population of the basin. Abstraction of
ground and surface water, together with agricultural and industri-
al activities, and the impact of waste-water treatment plants
(WWTPs), has deteriorated soil and water quality of some areas.
Pollution due to persistent organic pollutants, pesticides, bromi-
nated flame retardants and, more recently, pharmaceuticals and il-
llicit drugs, has been studied in the entire basin, and is very relevant
in some areas of the river (Barceló and Petrovic, 2011). The abun-
dant information gathered by the river basin authorities makes it
an excellent basin for controlled experiments.

The Adige is the second longest river in Italy, with a length of 410 km
and a drainage area of 12,000 km². Although the river is not within a dry
region, it is periodically affected by water scarcity. Climate is character-
ized by dry winters, snowmelt in the spring and humid summers and
falls. Because of the mountainous terrain and humid climate, the river
basin is well suited to hydroelectric production, and to date 30 major
reservoirs are in operation within the catchment, with a total storage
capacity of 571 Mm³, resulting in severely altered hydrology. The
main stressors in the basin are glacier melting, hydropower and pollu-
tion, especially associated to touristic activities. Earlier snow melting,
due to climate change, is already reducing water resources during the

![Conceptual links being considered within GLOBAQUA.](image-url)
irrigation period (June–August), while increased temperatures in summer months are expected to cause an increase in water demand and to accelerate glacier melting (Huss et al., 2010; Carturan et al., 2013). Diffuse pollution by agriculture in the central and lower course of the Adige River represents a relevant environmental pressure factor. Furthermore, hydropeaking can have severe consequences on the transport of contaminant loads. Additional potential stressors may include the release of pollutants accumulated in the glaciers, and the release of emerging pollutants from WWTPs.

The Sava River, the largest tributary of the Danube, is 945 km long and drains a catchment of 97,713 km². It is a transboundary river, and its management is therefore collaborative between the countries in the basin (Slovenia, Croatia, Bosnia and Herzegovina and Serbia). Although the pressures are similar to the Ebro, the hydrology is less variable. The population in the basin is about 8.2 million (46% of the total population of the four countries that share the basin) and is dependent on the Sava for drinking water. The upper reaches of the Sava basin are affected by hydromorphological pressures, the middle reaches by agricultural activities and eutrophication, and the lower reaches by industrial and urban pollution. The data available on the environmental status of the Sava River is currently limited to certain river sections or to particular variables (Torsten et al., 2008; Milacic et al., 2010).

The Evrotas River is one of the major rivers of the Peloponnese (Greece), with a length of 82 km and a drainage basin of 2418 km². Although not regulated, it is affected by overexploitation of water resources for irrigation, agro-industrial wastes (mainly oil mills), agrochemical pollution and geomorphological modifications. Overexploitation of groundwater aquifers and abstraction from surface waters result in the artificial desiccation of parts of the main stream and a number of tributaries (Skoulikidis et al., 2011). The time of desiccation and the hydroperiod of the remaining pools are critical for management and conservation purposes. Only one WWTP exists in the basin (city of Sparta), while villages are served by traditional permeable and impermeable cesspools. The amount of data available in the basin is very small.

The Souss Massa basin covers an area of 1486 km² in western Morocco, within a very arid region, where rainfall has decreased 20% during the last 30 years (ABHSM, 2008). The quality of water resources is affected by pollution from different sources (domestic, industrial, agricultural), thus resulting in a severe scarcity of water resources. The negative balance between water supply and demand, of 250 million m³ per year, is covered by groundwater mining, causing a lowering of the water table by 3 to 5 m per year and seawater intrusion in coastal areas (Arrifi, 2013). Most of the available natural water (95%) is used for agricultural purposes.

Finally, the Anglian River basin district (UK) is mostly low lying, spotted with fens (artificially drained coastal and estuarine wetlands) comprising a large proportion of the area (3188 km²). This results in over one fifth of the basin being susceptible to coastal and surface flooding. The area has intense horticulture and pig and poultry farming. Building is the largest economic sector in the basin, followed by manufacturing. The area is classified as seriously water stressed, with 20–45% of the effective rainfall currently abstracted for human consumption. The negative effects of water abstraction are exacerbated by a rapidly growing population. There is considerable background knowledge of this basin (Environment Agency, 2009; Collins et al., 2012) that will be used to undertake a comprehensive study of future scenarios.

4. Overview of methods

The case-study work within GLOBAQUA starts with the collection of existing data, so that the relation between stressors and ecological status can be assessed. The most suitable river reaches are being identified based on the information available on water scarcity, main stressors and
specific ecosystem services. Three different strategies are combined within GLOBAQUA: descriptive field campaigns, controlled field experiments, and manipulative experiments in the laboratory and in artificial streams. General information from the case-study basins will be gathered by means of simultaneous field sampling on pollutants, biodiversity and ecosystem functioning. In a subsequent step, field experiments will be performed on selected river segments to test the effect of combined stressors (e.g., WWTP inputs with sediment deposition; occurrence of specific pollutants and invasive species) on biodiversity and ecosystem functioning. They will be complemented with manipulative laboratory experiments, which will also address specific questions such as the interaction between water temperature and concentration of pharmaceutical concentrations. Combining field and lab experiments will allow understanding of the mechanisms behind the interactions between stressors as well as their effects on the different receptors.

Validated methods for chemical analysis of a broad spectrum of metals, priority and emerging pollutants in water, sediment and biota (algae, mussels, small aquatic organisms and fish) are already available. In addition, immunoassays and non-target screening will be used for the rapid characterization of contaminants. Quantitative sampling will be carried out on algae, macrophytes, invertebrates and fish, paying special attention to invasive species, and the weight of the different stressors on the community structure will be assessed by multivariate statistical tools. Field and laboratory bioassays (Damásio et al., 2011) and biomarker analysis will be performed to detect lethal and sub-lethal responses to chemicals. Ecosystem functioning will be evaluated by means of integrative processes such as retention of nutrients, removal of pollutants, whole-ecosystem metabolism, and decomposition of organic matter, which differ in the temporal and spatial scales at which they respond (Aristi et al., 2012).

Finally, the modelling approaches used in GLOBAQUA will include mechanistic models based on the River Water Quality Model (RWQM) (Reichert et al., 2001); InVEST (Tallis and Polasky, 2011), a spatially explicit tool consisting of a suite of models that use land use and land cover patterns to estimate levels and economic values of ecosystem services; and a suite of other modelling approaches to gain a better understanding of the hydrological processes at the catchment scale (mHM, GeoTransf, CATHY, WaSiM, SWAT). Also, existing spatially distributed water quality and water quantity hydrological models (LISFLOOD, LISQUAL) will be used to upscale results from the study areas to an EU-wide scale. Special effort will be made to combine the different models, climatic, hydrologic, hydromorphologic and so on, crossing the barriers among disciplines. An integrated methodology for identifying the environmentally and socioeconomically sustainable management of water resource ecosystem services will be performed in each case study. This methodology is consistent with the WFD and the three-step methodology proposed in the WATECO document for the implementation of the socio-economic aspects of the WFD. It is based on the concept of Total Economic Value of Ecosystem Services (Koundouri, 2009).

5. Detailed structure of GLOBAQUA

GLOBAQUA is organised in fourteen work-packages (WPs), grouped in five main modules (Fig. 3). All WPs will be implemented in all six case-study river basins, although fieldwork will not be performed in all of them to the same extent.

- **Module 1, STRESSORS (WPs 1 to 5):** it analyses the effects of water scarcity on the impacts of multiple stressors occurring in each study river basin, and forecasts the consequences of future scenarios for global change. It especially considers surface and groundwater hydrology, sediment transport, physical habitat, water quality, and the fate of inorganic and organic pollutants, and considers the consequences of different climatic, socio-economic and land-use scenarios.

- **Module 2, RECEPTORS (WPs 6 and 7):** it analyses the consequences of water scarcity and multiple stressors on biodiversity and ecosystem functioning. Research is based on field studies and manipulative laboratory experiments, combining artificial streams, reach-scale measurements, and basin-scale surveys to understand the effects of stressors at different scales, as well as modelling to forecast future scenarios.

![Fig. 3. Module and work-package structure of GLOBAQUA.](image-url)
• Module 3, IMPLICATIONS (WPs 8 to 10): it analyses the socio-economic implications of the effects of impacts on water quality and availability, as well as on biodiversity and ecosystem functioning, by translating the information gathered by modules 2 and 3 into ecosystem services, and investigating the effects on the socio-economic development.

• Module 4, ENVIRONMENTAL MANAGEMENT (WPs 11 and 12): it integrates the results of the other modules to define a manageable perspective of water scarcity for the studied river basins. It is, thus, an interface between scientific results of the project and their policy implications.

• Module 5, PROJECT COORDINATION AND DISSEMINATION (WPs 13 and 14): It is devoted to the communication of the results to target groups (researchers, policy makers, water managers, land planners, etc.), and to stimulating the use of results through relations with stakeholders and end-users. It also seeks to coordinate project activities.

WP1-DATA manages data either internally generated by the project or acquired from external sources, and conveys them to a Hub platform to share the data among project members, and eventually among potential users, either scientists or managers.

WP2-SCENARIOS draws data stored by WP1-DATA to produce spatially explicit, integrated scenarios of environmental change for each case study, including climatic, socio-economic and land use factors. The primary climate model data set will be an ensemble of 1960–2100 transient runs performed with the RCA4 model at 50 km and 12.5 km. Comparisons will focus on the 2050 time horizon (2041–2070) versus the reference climatology (1981–2010). It encompasses numerous GCMs (~10) and RCMs (~6), as well as 3 of the CMIP5 Reference Concentration Pathways (RCPs 2.6, 4.5, and 8.5). The RCA4 data set will be complemented with data from other RCMs in EURO-CORDEX (Kjellström et al., 2013). The climate model data will further be biased-corrected to sufficiently reproduce the reference climatology. Finally, the climate data is spatially scaled to account for fine scale heterogeneities in complex terrain, using a model interface that superimposes spatially explicit, integrated scenarios of environmental change for each case study, including climatic, socio-economic and land use factors.

WP3-HYDROL uses existing modelling approaches to link surface and subsurface hydrological fluxes and the impact of water scarcity on the ecological status of streams, including hyporheic, riparian and floodplain zones. Flow and transport processes are upscaled from point to basin and regional scales, accounting for the sources of uncertainty of the model outputs. Historical data series are analysed to disentangle the effect of multiple human impacts on water resources along time and across space. This WP uses global change scenarios built in WP2-SCENARIOS and data gathered in WP1-DATA, and provides information to WP4-GEOMORPH, WP6-BIOL, WP7-ECOSYSTEM and WP8-SERVICES.

WP4-GEOMORPH analyses the effects of changing hydrology, land use, and climate on sediment transport, channel morphology, physical habitat, and pollutant fluxes in rivers. It analyses the sediments as vectors for contaminant transport (Rügner et al., 2013; Schwientek et al., 2013) and retention, and the geomorphological change as driver of other impacts on fluvial communities. Thus, it has strong links with WP3-HYDROL (processes at the surface/subsurface boundaries), and with WPs-QUALITYCHEM (contaminant transport associated to sediments) and WP6-BIOL (impact of geomorphologic changes on habitats and communities).

WP5-QUALITYCHEM studies chemical contaminants, both inorganic and organic, and their relationship to the ecosystem status, providing data to the WPs of the module RECEPTORS. It analyses the occurrence, fate and behaviour of priority and emerging pollutants in rivers (heavy metals, halogenated and organophosphate compounds, pharmaceuticals and hormones, personal care products, pesticides, perfluorinated compounds and nanomaterials), and identifies the effects of water scarcity across study basins. This WP combines general sampling surveys, field and laboratory experiments to test the effects of multiple pressures on the fate and behaviour of microcontaminants.

WP6-BIOL quantifies the effects of water scarcity and other stressors on river biodiversity, including bacteria, primary producers (algae, macrophytes), invertebrates, and fish, and how this affects biological traits and functional diversity (Statzner and Bêche, 2010). It pays special attention to the impairment of key habitats as it can reduce species resistance capacity and promote the spreading of invasive species (Rahel, 2007). On-site analyses are combined with field and mesocosm experiments, studying the changes induced by pathogens, micropollutants and invasive species on biodiversity in each study basin.

WP7-ECOSYSTEM assesses ecosystem functions at different spatial and temporal scales, by measuring processes such as nutrient retention, removal of pollutants, or whole-ecosystem metabolism (Palmer and Febría, 2012). Additionally, whole-river metabolism is reconstructed from historical data on oxygen concentration to determine the effects of climatic variation and new human stressors of known occurrence on river ecosystem functioning. The historical perspective of human occupancy and land use change is assessed through analyses of historic adjustment of river channels.

WP8-SERVICES uses the information on ecosystem functioning to establish cause–effect relationships between stressors and ecosystem services. Thus, it provides objective tools for decision systems to evaluate the effects of planned management interventions and to help planners manage the river basin as a whole. Taking decisions to counteract the effects of multiple stressors on ecosystem attributes such as ecological or chemical status. The transversal component of WP8-SERVICES within GLOBAQUA requires a close relationship to WP6-BIOL, WP7-ECOSYSTEM, WP9-SOCIOECON, WP10-VALUATION and WP11-INTEGRATION.

WP9-SOCIOECON analyses the effects of water scarcity and multiple stressors on the socio-economic development of the case-study regions, in a case-study driven approach. This relies on the flow of information from and to WP8-SERVICES and WP10-VALUATION, and follows three steps: socioeconomic characterization, estimation of the percentage of cost-recovery of water uses, and development of the package of socio-economic measures to achieve good water status (Koundouri, 2009). The outputs of WP9-SOCIOECON correspond directly to the WFD’s Articles 5 and 9 and Annex III.

WP10-VALUATION aims to assess the economic effects derived from the interaction of multiple stressors on aquatic ecosystems under water scarcity. This WP analyses how biophysical changes in ecosystems are affecting human well-being, taking into account the users’ perspective and valuation of ecosystem services. Participative workshops are organised to validate this perspective, and the outputs will integrate findings for the WP12-POLICY and the dissemination activities of WP13-DISSEMINATION.

WP11-INTEGRATION uses the information generated by the other WPs to integrate the main consequences of water scarcity for biodiversity and the human society. Therefore, it integrates across disciplines, from biophysical to the socio-economic fields, considering the complex of abiotic and biotic interacting as ecosystem functions, and across scales, from river reach to basin and regional scale, towards a pan-European view.

WP12-POLICY connects the impact of scarcity with water policy, following a systems approach that acknowledges the critical role of socio-economic policy instruments and investment for WFD implementation, and building on the findings of all WPs. Therefore, this WP defines the current EU context, identifies opportunities to assist policy making, and will produce recommendations for improvement.

WP13-DISSEMINATION ensures the communication of results to specific target groups (researchers, policy makers, water managers,
land planners, etc.), through relations with stakeholders and end-users and through training programmes for different end-users.

WP14-MANAGEMENT assists the coordinator to achieve the planned results and their maximum impact, as well as the transfer of results to stakeholders. For this, a special External Advisory Board is established, which will peer review the results, control the quality of deliverables, and suggest how to improve the outputs of the project to the needs of stakeholders.

6. Final remarks

Water scarcity already exerts strong environmental pressures in many European regions, and is a serious cause of concern in many more, according to scenarios of future environmental change. Therefore, it is crucial to gain sound scientific information on the ways water scarcity interacts with other stressors in freshwater ecosystems, in order to understand its environmental and socio-economic consequences, and to convey this information to managers, stakeholders and policymakers in order to minimise impacts, to adapt to oncoming changes, and to improve our management and policies. These are the main tasks of GLOBAQUA, a project that brings together a large group of researchers, stakeholders, and policy makers across a wide range of disciplines. The added value of this collaboration lies in the possibility of addressing the problems arising from the scarcity and multiple stressors, as well as their effects on the ecosystem services and the overall effects of global changes. Hopefully, the close collaboration between scientist and stakeholders in GLOBAQUA, will allow implementing the approaches proposed in pilot sub-basins within the study areas, and to better fulfill water needs of both human and nature.

Acknowledgements

This work has been supported by the European Communities 7 Framework Programme Funding under Grant agreement no. 603629-ENV-2013-6.2.1-Globaquà and by the Generalitat de Catalunya (Consolidated Research Groups “2014 SGR 418 - Water and Soil Quality Unit” and 2014 SGR 291 - ICRA). Damià Barceló acknowledges support from the Visiting Professor Program of King Saud University. Special thanks are due to all partners of the GLOBAQUA consortium and the peer review panel for providing quality results and fruitful collaboration within the project.
