#### Abstract

 Filters are essential for guaranteeing the good performance of microirrigation systems. Pressure losses across filters should be known for the proper design and management of this irrigation equipment. Pressure losses produced by filtering media in sand filters can be computed using Ergun or Kozeny-Karman equations, which require knowledge, among other parameters, of the sphericity of the filter medium. As this parameter is not easy to determine, it is useful to explore the performance of alternative computing methods that can avoid requiring knowledge of sphericity. In this paper, taking as starting point the nonparametric machine learning approach known as the gradient boosted regression tree (GBRT) approach and hybridising it with the differential evolution (DE) technique, the pressure drop in sand filters used in microirrigation has been modelled. For different filtering materials such as modified glass, crushed glass, silica sand and glass microspheres, experimental data of pressure drop for velocities between 0.004 and 0.025 22 m s<sup>-1</sup> was collected and the model built. The results demonstrated that DE–GBRT–based model was able to accurately predict pressure drop. The model also allowed ranking of

## 34 1. Introduction

 Proper irrigation water filtration is essential to ensure the successful continuous long-term operation of microirrigation systems (Clark, Haman, Prochaska, & Yitayew, 2007). By following good maintenance practices, which includes filtration, the longevity of some subsurface microirrigation systems have reached 26.5 years (Lamm & Rogers, 2017). Screen, disc, media and hydro-cyclone filters are common filter types that are used in microirrigation systems. The choice of filter type will basically depend on the quality of  water source, the flow rate of the irrigation system and the desired filtered water quality for avoiding emitter clogging (Clark et al, 2007).

 Irrigation engineers require knowledge of the pressure drop across the filter to properly design and manage this important system component which is related to water and energy consumption as well as pollutant removal efficiency (Duran-Ros, Puig-Bargués, Arbat, Barragán, & Ramírez de Cartagena, 2009). Mathematical models have been developed using dimensional analysis for describing pressure drops across screens (Wu, Chen, Liu, Yin, & Niu, 2014b; Zong, Zheng, Liu & Li, 2015), disc (Yurdem, Demir, & Degirmencioglu, 2008; Wu et al., 2014a), hydrocyclone (Yurdem, Demir, & Degirmencioglu, 2008) and in sand media filters (Elbana, Ramírez de Cartagena, & Puig- Bargués, 2013). These models did not consider the specific effect of the different filter components (filtration zone and auxiliary elements) on pressure loss. In sand media filters, pressure loss clearly vary across the filter media, the underdrain and diffuser platter, and the backflushing valve (Bové et al., 2015b; Burt, 2010; Mesquita, Testezlaf & Ramirez, 2012).

 Bové et al. (2015a) experimentally analysed the pressure drop across different sand and recycled glass media in a microirrigation sand filter. Although the Ergun equation showed the best prediction accuracy for predicting the pressure drop, multi linear regression equations had better performance than the Kozeny–Carman equation, which is a simplification of the Ergun equation. However, these equations require parameters defining the filter media such as equivalent diameter and sphericity which are difficult to obtain.

 García-Nieto et al. (2017) used a hybrid model artificial bee colony (ABC)-multivariate adaptive regression splines (MARS) which satisfactorily computed pressure loss across filtration beds without the need for sphericity. This work suggests that other alternative methods, specifically a hybrid methodology that combines the gradient boosted regression tree (GBRT) approach with the differential evolution (DE) optimisation algorithm (Storn, & Price, 1997; Price, Storn, & Lampinen, 2005; Feoktistov, 2006; Rocca, Oliveri, & Massa, 2011), could also be used to predict pressure drops in the granular filters used in microirrigation systems.

 GBRT models are supervised machine learning procedures that can be used for multivariate classification and regression (Vapnik, 1998; Friedman, 2002; Schapire, 2003; Bühlman & Hothorn, 2007; Hastie et al., 2003). GBRT models build competitive, highly robust procedures that are particularly appropriate for treating not very clean data (Hastie et al., 2003). They are very flexible models that can be easily be customised for any data-driven task. They are straightforward to implement and have been very successful in data-mining and machine-learning challenges (Natekin & Knoll, 2013). One of the reasons for their success could be that tree boosting takes the bias-variance trade- off into consideration while fitting the models (Nielsen, 2016). For example, GBRT models have been effective in predicting biological parameters in environmental problems such as forecasting wind variables (Landry et al., 2016), solar power generation 85 prediction (Persson et al., 2017) and short-term waste estimation (Johnson et al., 2017).

86 and the set of the

 Differential evolution (DE) is a metaheuristic evolutionary global method, derived from genetic algorithm (GA), intrinsically capable of solving multidimensional optimisation  problems involving continuous variables. As with other evolutionary computation algorithms such as particle swarm optimisation (PSO) (Eberhart et al., 2001; Clerc, 2006; Olsson, 2011) or ant colony optimisation (Dorigo & Stützle, 2004), DE is a bio-inspired algorithm that generates high-quality solutions to optimisation problems by means of bio- inspired operators such as mutation, recombination and selection (Storn & Price, 1997; Price, Storn & Lampinen, 2005; Simon, 2013; Yang et al., 2013). 99 procedures intertaing committed variables. 99 algorithms such as particle swarm optimisation (PSO) (Eberhart et al., 2001; Clerc, 2006;<br>
91 Olisson, 2011) or ant colony optimisati

 The main objective of the present study was to develop a hybrid algorithm using DE optimising GBRT parameters (DE–GBRT) to predict the pressure drop per unit length filtration media used in media filters.

### 2. Materials and methods

2.1. Experimental setup

 The experimental setup providing the considered data set is described in Bové et al. (2015a). In a laboratory filter, which was a scaled version of a commercial microirrigation media filter (Arbat et al., 2013), pressure losses of four different filtration materials (silica sand, crushed recycled glass, surface modified glass and microspheres) with grain sizes between 0.63 and 1.50 mm were measured at surface velocities ranging from 0.004 to 0.025 m s-1 under pressures ranging between 4,631 and 275,630 Pa.

Data obtained from the experiment gave the pressure drop per unit length  $(\Delta p / \Delta L)$ , as<br>the output variable. The input variables were the filter media type (as category), media<br>bulk and real density, porosity, equivalent the output variable. The input variables were the filter media type (as category), media bulk and real density, porosity, equivalent diameter, sphericity or shape factor, flow surface velocity and average grain size. Procedures for obtaining these variables are described in Bové et al. (2015a).

116

117 2.3. Computational procedure

118 2.3.1. Gradient boosting regression tree (GBRT)

 Gradient boosting is a machine learning method used for classification and regression that constructs a model from a set of weak models or learners, that are, usually, decision trees. It builds the model by stages, as is typical for boosting methods, and obtains a single strong ensemble model optimising a differentiable loss function (Breinman et al. 1984; Vapnik, 1998; Friedman et al., 2000; Friedman, 2001; Friedman, 2002; Schapire, 2003; Bühlman & Hothorn 2007; Hastie et al., 2003). 119 Gradient boosting is a machine learning method used for classification and regression that<br>

 Gradient boosting can be used with decision trees, in particular with CART, of a given fixed size as weak learners. For this particular situation, Friedman (Friedman, 2002) proposes a variation of the gradient boosting method that improves each weak learner quality of fit (Friedman, 2002; Ridgeway, 2007; Hastie et al., 2003; Taieb & Hyndman, 2014; Döpke et al., 2017). $$

 Friedman (Shapire, 2003; Bühlmann, & Hothorn, 2007) proposed a modification of this 187 algorithm that chooses a different optimal  $\gamma_{jm}$  for each of the regions, instead of only one  $f_{m}$  for the whole tree. This modified algorithm is called TreeBoost. Then, the model is updated (Bühlmann & Hothorn, 2007; Hastie et al., 2003; Taieb & Hyndman, 2014; Döpke et al., 2017):

$$
F_m(x) = F_{m-1}(x) + \sum_{i=1}^{J_m} \gamma_{jm} I(x \in R_{jm}); \quad \gamma_{jm} = \arg\min_{\gamma} \sum_{x_i \in R_{jm}} L(y_i, F_{m-1}(x_i) + \gamma) \tag{11}
$$
  
the size of trees, *J*, is the number of terminal nodes in trees and it is a parameter

 $\gamma_1(x) + \sum_{i=1}^{J_m} \gamma_{jm} I(x \in R_{jm});$   $\gamma_{jm} = \arg \min_{\gamma} \sum_{x_i \in R_{jm}} L(y_i, F_{m-1}(x_i) + \gamma)$  (11)<br>ees, *J*, is the number of terminal nodes in trees and it is a parameter<br>at for the training data set. It controls the interaction level  $\sum_{m}^{n} (x) = F_{m-1}(x) + \sum_{i=1}^{J_m} \gamma_{jm} I(x \in R_{jm});$   $\gamma_{jm} = \arg \min_{\gamma} \sum_{x_i \in R_{jm}} L(y_i, F_{m-1}(x_i) + \gamma)$  (11)<br>  $\gamma_{m}$  is the number of terminal nodes in trees and it is a parameter<br>
the adjusted for the training data set. It control  $\sum_{i=1}^{J_m} \gamma_{jm} I(x \in R_{jm});$   $\gamma_{jm} = \arg \min_{\gamma} \sum_{x_i \in R_{jm}} L(y_i, F_{m-1}(x_i) + \gamma)$  (11)<br>is the number of terminal nodes in trees and it is a parameter<br>ne training data set. It controls the interaction level between 191 where the size of trees, J, is the number of terminal nodes in trees and it is a parameter 192 that can be adjusted for the training data set. It controls the interaction level between 193 variables in the model. If  $J = 2$  (decision stumps), there is no interaction between 194 variables. With  $J = 3$  the model can allow interactions between up to two variables, and 195 so on. Typically a value between 4 and 8 works well and the results are quite insensitive  $F_m(x) = F_{m-1}(x) + \sum_{i=1}^{l_m} \gamma_{jm} I(x \in R_{jm})$ ;  $\gamma_{jm} = \arg \min_{x} \sum_{x_i \in R_{jm}} L(y_i, F_{m-1}(x_i) + \gamma)$  (11)<br>
where the size of trees, *J*, is the number of terminal nodes in trees and it is a parameter<br>
that can be adjusted for the trai 197 unnecessary.

198

199 Overfitting the training set can lead to a poor prediction ability. The regularisation 200 techniques are intended to reduce this overfitting effect controlling the training process.

201

 There are different approaches to attain this aim (Bühlmann and Hothorn 2007; Hastie et al., 2003; Taieb & Hyndman 2014; Döpke et al., 2017). In particular, the technique used by the function GBRT is to include in the loss function the so called penalty function whose aim is to limit the overfitting: ad to a poor prediction ability. The *regularisation*<br>is overfitting effect controlling the training process.<br>tain this aim (Bühlmann and Hothorn 2007; Hastie et<br>Döpke et al., 2017). In particular, the technique used<br>e in

$$
L(x) = E(x) + \Omega(x) \tag{12}
$$

206 where E can be, for instance, the mean squared error, and  $\Omega$  is the penalty function that 207 controls the model complexity, aiding to avoid overfitting by means of increasing the 208 value of the loss function when the complexity of the model grows, thus penalising it.

## 2.3.2. The differential evolution (DE) algorithm

 In evolutionary computation, differential evolution (DE) is a metaheuristic method that optimises a problem by iteratively trying to improve a candidate solution with regard to a given measure of quality. DE is used for multidimensional real-valued but does not require for the optimisation problem to be differentiable. Therefore, DE can also be used for optimisation problems that are not continuous, are noisy, and change over time, etc. DE optimises a problem by maintaining a population of candidate solutions and creating new candidate solutions by combining existing ones according to its simple formulae, and then keeping whichever candidate solution has the best fitness on the optimisation problem at hand (Storn & Price, 1997).

 The algorithm assumes that the variables of the problem to be optimised are encoded as 245 a vector of real numbers. The length  $n$  of these vectors is equal to the number of variables 246 of the problem, and the population is composed of  $NP$  vectors (number of parents). A 229 DE optimisation proofens that are not commissed, are notisy, and stating over thme, etc.<br>
229 DE optimises a problem by maintaining a population of candidate solutions and creating<br>
240 approximation by combining exis  $\mathbf{x}_p^g$  is defined, where p is the 249 new candidate solutions by combining existing ones according to its simple formulae, and<br>
241 then keeping whichever candidate solution has the best fitness on the optimisation<br>
242 problem at hand (Storn & Price, 199 241 then keeping whichever candidate solution has the best fitness on the optimisation<br>242 problem at hand (Storn & Price, 1997).<br>243<br>244 The algorithm assumes that the variables of the problem to be optimised are encoded the variables of the problem  $x_{p,m}^g$ , where *m* is the index of the variable in the individual modidate solution has the best fitness on the optimisation<br>ice, 1997).<br>the variables of the problem to be optimised are encoded as<br>length *n* of these vectors is equal to the number of variables<br>ulation is composed of *NP* 242 problem at hand (Storn & Price, 1997).<br>
243<br>
244 The algorithm assumes that the variables of the problem to be optimised are encoded as<br>

244 The algorithm assumes that the variables of the problem to be optimised are encoded as<br>
245 a vector of real numbers. The length *n* of these vectors is equal to the number of variables<br>
245 of the problem, and t  $\mathbf{x}_{m}^{\min}$  and  $\mathbf{x}_{m}^{\max}$ , respectively. Hence, DE technique is basically composed of four steps:

 Initialisation; Mutation; Recombination; and Selection.

257 Initialisation is performed at the beginning of the search, and the mutation-recombination-258 selection steps are performed repeatedly, until a termination condition or stopping 259 criterion is satisfied (number of generations, elapsed time, or quality of solution reached, 260 etc.). ation is performed at the beginning of the search, and the mutation-recombination-<br>

$$
 (14)

269 with p, a, b and c different from each other. F is a parameter that controls the mutation

271 Recombination

272 After obtaining the NP noisy random vectors, the recombination is performed in a random 267 individuals chosen at random, called target vectors  $\mathbf{x}_a$ ,  $\mathbf{x}_b$  and  $\mathbf{x}_c$ . The noisy random<br>
268 vectors  $\mathbf{n}'_p$  are obtained as follows:<br>  $\mathbf{n}^z_p = \mathbf{x}_c + F \cdot (\mathbf{x}_a - \mathbf{x}_b)$  for  $p = 1,..., NP$  (14)<br>
269 with p  $\mathbf{x}_p^g$ , obtaining the trial vectors  $\mathbf{t}_m^g$  as  $\frac{g}{m}$  as 274 follows:

$$
t_{p,m}^g = \begin{cases} n_{p,m}^g & \text{if } rand(0,1) < GR \\ x_{p,m}^g & \text{otherwise} \end{cases} \text{ for } p = 1,..., NP \text{ and } m = 1,..., n \tag{15}
$$
\n
$$
\text{parameter that controls the recombination rate. Note that the comparison is carried}
$$

275 GR is a parameter that controls the recombination rate. Note that the comparison is carried 276 out variable by variable, so that the test vector will be a mixture of the noisy random 277 vectors and original vectors.

278 Selection

279 Finally, the selection is made simply by comparing the test vectors with the original ones, 280 so that the vector of the next generation will be the one that has the best value of the 281 fitness function fit: erwise  $\int$  for  $p = 1, ..., n$  and  $m = 1, ..., n$ <br>
are recombination rate. Note that the comparison is carried<br>

$$
 (16)

## 282 2.4. The goodness-of-fit of this approach

283 The operation physical input variables considered in this research work are shown in 284 Table 1. Therefore, the total number of predicting variables used to construct the hybrid 285 DE–GBRT-based model was eight. The output predicted variable is the pressure drop per 280 so that the vector of the next generation will be the one that has the best value of the<br>
281 finess function fit:<br>  $x_p^{s-t} = \begin{cases} t_p^s & \text{if } \int f^i(t_p^s) > f^i(t_p^s) \end{cases}$  (16)<br>  $x_p^{s-t} = \begin{cases} t_p^s & \text{if } \int f^i(t_p^s) > f^i(t_p^s) \end{cases$ 283 The operation physical input variables considered in this research work are shown in<br>
2014 Table 1. Therefore, the total number of predicting variables used to construct the hybrid<br>
2015 DE-GBRT-based model was eight.

287

288 Table 1 - Set of operation physical input variables used in this study and their names 289 along with their mean and standard deviation.

290

292 it is necessary to choose the model that best fits the experimental data. To determine the

293 goodness–of–fit, the two criteria considered here were the coefficient of determination  $R^2$ 294 and the root mean square error (RMSE), respectively (Freedman et al., 2007). A dataset 293 goodness-of-fit, the two criteria considered here were the coefficient of determination  $R^2$ <br>294 and the root mean square error (*RMSE*), respectively (Freedman et al., 2007). A dataset<br>295 takes values  $t_i$ , each of  $t_i$ , each of which has an associated modelled value  $y_i$ . The former are termed 296 the observed values and the latter are often referred to as the predicted values. The dataset 297 variability is measured through different sums of squares as follows (Freedman et al., 298 2007):

• 
$$
SS_{tot} = \sum_{i=1}^{n} (t_i - \bar{t})^2
$$
: the total sum of squares, proportional to the sample variance.

300 •  $SS_{res} = \sum_{i=1}^{n} (y_i - \overline{t})^2$ : the regression sum of squares, also termed the explained sum  $i=1$  $SS_{reg} = \sum (y_i - \bar{t})^2$ : the regression sum of  $1$ 2  $\alpha$   $\alpha$ 

301 of squares.

302 
$$
\bullet \quad SS_{err} = \sum_{i=1}^{n} (t_i - y_i)^2 \text{ : the residual sum of squares.}
$$

303 Note that in the previous sums,  $\bar{t}$  is the mean of the *n* observed data:

$$
\bar{t} = \frac{1}{n} \sum_{i=1}^{n} t_i
$$
 (17)

304 Taking into account the above sums, the coefficient of determination is defined via:

$$
R^2 \equiv 1 - \frac{SS_{err}}{SS_{tot}} \tag{18}
$$

305 so that a coefficient of determination value of 1.0 points out that the regression curve fits 306 the data perfectly.

307

308 Similarly, the second ratio used in this research work to measure the goodness–of–fit is 309 the root mean square error (RMSE). It indicates the sample standard deviation of the 310 differences between predicted values and observed values. The *RMSE* is defined for n different predictions as follows (Freedman et al., 2007):

$$
RMSE \equiv \sqrt{\frac{SS_{err}}{n}}
$$
 (19)

### 2.3.3. The hybrid DE-GBRT-base model

 Additionally, as previously mentioned, the GBRT technique is greatly dependent on the GBRT hyperparameters such as the maximum number of iterations (Nrounds), learning rate, minimum loss reduction, minimum child weight, maximum step and subsample ratio. Some methods frequently used to determine suitable hyperparameters are (Hastie, Tibshirani, & Friedman, 2003): grid search, random search, Nelder-Mead search, heuristic search, genetic algorithms, pattern search and so on. Usually, the traditional way 319 of performing hyperparameter optimisation has been *grid search*, or a *parameter sweep*, which selects sets of parameters from a chosen grid and studies the performance of the model for each set. Indeed, the grid search is a brute force method and, as such, almost any optimisation method improves its efficiency. In this study, in order to avoid these problems associated with the grid search method, the differential evolution (DE) metaheuristic technique was used (Price, Storn, & Lampinen, 2005; Simon, 2013; Yang et al., 2013).

 The DE optimisation technique was selected as ait appeared to be an appropriate, effective and simple tool for tuning the GBRT parameters. A hybrid model, specifically a novel hybrid DE–GBRT–based model, was constructed taking as its dependent variable the pressure drop per unit length (output variable) from the other eight remaining variables (input variables) found in granular filters (Bové et al., 2015a), studying their effect in  order to optimise its calculation through the analysis of the coefficient of determination 333  $R^2$  with success. Fig. 1 shows the flowchart of this new hybrid DE–GBRT–based model implemented in this research work.

Fig. 1 - Flowchart of the new hybrid DE–GBRT–based model.

 Furthermore, cross-validation was the standard technique utilised here for finding the real order to optimise its calculation through the analysis of the coefficient of determination<br>  $R^2$  with success. Fig. 1 shows the flowchart of this new hybrid DE-GBRT-based model<br>
implemented in this research work.<br>
335<br>
F in order to assessment the predictive capacity of the DE–GBRT–based model, a thorough 10-fold cross-validation algorithm was implemented in this study (Picard & Cook, 1984). To this end, the regression modelling has been performed with the Extreme Gradient 343 Boosting algorithm, using the Xgboost library (Chen, He, Benesty, Khotilovich & Tang, 344 2017) along with the DE technique with the DEoptim package (Ardia, Mullen, Brian,  $\&$  Peterson, 2016) from the R Project. The initial intervals of the space of solutions used in DE technique are indicated in Table 2. 349 process stopped if the value of the relative tolerance (10<sup>-8</sup>) could not Extreme Gradient<br>341 10-fold cross-validation algorithm was implemented in this study (Picard & Cook, 1984).<br>342 To this end, the regression mo

 It should be noted that sixty population members were used in the DE optimisation. The process stopped if the value of the relative tolerance  $(10^{-8})$  could not be reduced after 30 steps or a maximum number of 200 iterations. Under this conditions, the tuning of the parameters required 89 iterations in order to get convergence.

Table 2 - Search space for each of the GBRT parameters in the DE tuning process.

 In order to optimise the GBRT parameters, the DE module was used. In this way, the DE looks for the best parameters (maximum number of iterations (rounds), learning rate, minimum loss reduction, minimum child weight, maximum step and subsample ratio) by using the comparison of the cross-validation error in every iteration. The search space is six-dimensional, with one dimension per each parameter. Hence, the objective function 355 In order to optimise the GBRT parameters, the DE module was used. In this way, the DE<br>366 looks for the best parameters (maximum number of iterations (rounds), learning rate,<br>357 minimum loss reduction, minimum child 3. Results and discussion Table 3 points out the optimal hyperparameters of the best fitted DE–GBRT–based model found with the differential evolution (DE) technique. Table 3 - Optimal hyperparameters of the best fitted GBRT model found with the DE technique. Table 4 shows the determination and correlation coefficients for the hybrid DE–GBRT– based model fitted for the pressure drop per unit length in this article. 364 Table 3 - Optimal hyperparameters of the best fitted GBRT model found with the DE<br>365 Table 3 - Optimal hyperparameters of the best fitted GBRT model found with the DE<br>366 Table 4 shows the determination and correlati square errors (RMSE) for the hybrid DE–GBRT–based model fitted in this study for the pressure drop per unit length. 

 According to these previous statistical calculations, the GBRT technique in combination with the DE optimization is an excellent model for estimating the pressure drop per unit length in granular filters, since the fitted GBRT model with DE has a coefficient of 376 According to these previous statistical calculations, the GBRT technique in combination<br>377 with the DE optimization is an excellent model for estimating the pressure drop per unit<br>378 length in granular filters, sinc

 These coefficients are similar to those obtained by García-Nieto et al. (2017) using an ABC-MARS model, altough the RMSE was slightly smaller with the DE-GBRT model. So, these results show a trustworthy goodness of fit, that is to say, a good agreement is obtained between our model and the observed data.

 An iMac with a processor 3.2 GHz Intel Core i5, with 8GB RAM and Maverick 10.9.5 as operating system was used to perform the computation. A time of 773.984 s, approximately 12 min, was necessary for the tuning and construction of the model.

 The importance measure are relative and the addition of all the values for each criteria amounts to one. They are:

392 Gain: it is computed taking into account each variable contribution to each tree that appears in the model.

394 Cover: it is the relative number of observations of the variable in the model.

395 Frequency: it is the relative number of times an independent variable appears in the trees of the obtained model.

397 The most significant measaure is *Gain* and thus it has been used to contruct the graph of the relative importance of the variables.

 As an additional result of these calculations, the significance ranking for the three input variables predicting the pressure drop per unit length (output variable) in this complex study is shown in Table 5 and Fig. 2. Therefore, for the DE–GBRT model the most significant variable in pressure drop per unit length prediction is the Flow surface velocity, followed by Average grain size, and finally equivalent diameter. 405 based model for the pressure drop per unit length (output variable) in this complex<br>400 variables predicting the pressure drop per unit length (output variable) in this complex<br>401 study is shown in Table 5 and Fig. 2

404 **Table 5** - Significance ranking for the variab

Fig. 2 - Relative importance of the input operation variables to predict the pressure drop

 Bearing in mind that the flow surface velocity and average grain size are two variables easy to determine experimentally and the GBRT model indicates that they are the two most important variables, a simplified GBRT model was built using only these two variables. The curve predicted with this model is compared with the observed one in Fig. 3. The determination coefficient and correlation coefficient for this simplified model were 0.78 and 0.88, respectively.

 In conclusion, this work was able to estimate the pressure drop per unit length in agreement with the actual experimental values observed using the DE–GBRT–based model with great accurateness as well as success. Therefore, it was appropriate to use a  GBRT model with a DE–based optimisation technique in order to achieve the best effective approach in this regression problem. Because these results agree with the 422 GBRT model with a DE-based optimisation technique in order to achieve the best<br>423 effective approach in this regression problem. Because these results agree with the<br>424 outcome criterion of 'goodness of fit' ( $R^2$ ) fit to the experimental. **GBRT** model with a DE-based optimisation technique in order to achieve the best<br>423 effective approach in this regression problem. Fig. 3 - Comparison between the pressure drop per unit length values observed and

 Finally, the residual errors for each observation of the predicted model, calculated as the difference between the predicted and the observed pressure drop per unit length values, by type of filter, using the DE–GBRT–based simplified model, is represented in Fig. 4.

434 Fig. 4 – Residuals for the predicted pressure drop per unit length values, by type of filter, using the DE–GBRT–based simplified model.

## 4. Conclusions

 Taking into account the experimental and numerical results, the main findings of this study can be summarised as follows:

 The new hybrid DE–GBRT–based model used in this work can accurately predict the pressure drop per unit length in different granular media used in sand filters without using as input variable the sphericity, which is a parameter difficult to obtain experimentally.

 A reasonable coefficient of determination equal to 0.78 was obtained when this hybrid DE–GBRT–based model was applied to the experimental pressure drop dataset.

 The significance order of the input variables involved in the prediction of the pressure drop per unit length in granular filters was set. This is one of the main findings in this work. Specifically, input variable Flow surface velocity could be considered the most influential parameter in the prediction of the pressure drop per unit length. In this regard, it is also important to highlight the influential role of the Average grain size in the dependent variable pressure drop per unit length.

 Taking into account the results of the previous point, and for practical reasons, as the two most important variables are relatively easy to obtain, a simplified GBRT model that used only these variables was developed with a comparatively very good coefficient of determination.

 The influence of the hyperparameters involved in the GBRT approach to predict pressure drop per unit length regression performance was established.

 The results verified that the hybrid DE–GBRT–based regression method significantly improved the generalisation capability achievable with only the GBRT–based regressor. Thus, input data from other filtered materials used in microirrigation can be processed to predict the pressure drop measuring only a few key variables.

 In summary, this innovative methodology presented could be applied to other filtration processes with similar or distinct filter media types with success, but it is always necessary to take into account the characteristics of each filter and experiment. Consequently, an effective DE–GBRT–based model is a good practical solution to the  problem of predicting the pressure drop in sand media filters that are used in microirrigation systems.

## Acknowledgements

 Authors wish to acknowledge the computational support provided by the Department of Mathematics at University of Oviedo as well as financial support of the Spanish Ministry of Economy and Competitiveness through Grant AGL2015-63750-R. Additionally, we would like to thank Anthony Ashworth for his revision of English grammar and spelling of the manuscript.
